A.1 Rescaled model equations

The following relations are used (lower-case letters denote dimensionless variables):

\[
\begin{align*}
  s_i &= \frac{S_i}{K_i}, \\
  b &= \frac{B}{K_1 Y_1} w_1, \\
  e_i &= \frac{E_i}{Y_1}, \\
  x_i &= \frac{X_i}{k_{s1} Y_1 k_{xi}}, \\
  m &= \frac{M}{k_{s1} Y_1 k_m}, \\
  b' &= \frac{B'}{Y_1}, \\
  \tau &= k_{s1} t, \\
\end{align*}
\]

(A.1)

and the following system of ODEs is obtained (the derivative is with respect to dimensionless time \(\tau\)):

\[
\begin{align*}
  \dot{s}_1 &= -\frac{e_1 s_1}{1 + s_1} b, \quad s_1(0) = s_{10}, \\
  \dot{s}_2 &= -k_s K_s w_s \frac{e_2 s_2}{1 + s_2} b, \quad s_2(0) = s_{20}, \\
  \dot{b} &= \mu b, \quad b(0) = b_0, \\
  \dot{e}_1 &= k_{e1} f_1 - \mu e_1, \quad e_1(0) = e_{10}, \\
  \dot{e}_2 &= k_{e2} f_2 - \mu e_2, \quad e_2(0) = e_{20}, \\
  \dot{x}_1 &= \frac{e_1 s_1}{1 + s_1} - x_1, \quad x_1(0) = x_{10}, \\
  \dot{x}_2 &= k_s \frac{e_2 s_2}{1 + s_2} - x_2, \quad x_2(0) = x_{20}, \\
  \dot{m} &= x_1 + x_2 - m, \quad m(0) = m_0, \\
  \dot{b'} &= m - \mu b', \quad b'(0) = b'_0, \\
\end{align*}
\]

(A.2)
with the following abbreviations:

\[
\begin{align*}
  k_s &= \frac{k_{s2}}{k_{s1}}, & K_s &= \frac{K_{s1}}{K_{s2}}, & w_s &= \frac{w_2}{w_1},
  \\
  k_{e1} &= Y_1 \frac{k_1}{K_{s1}}, & k_{e2} &= Y_1 \frac{k_2}{K_{s1}}, & Y &= \frac{Y_2}{Y_1}
\end{align*}
\]  

(A.3)

and the specific growth rate \( \mu \):

\[
\mu = \frac{e_1 s_1}{1 + s_1} + k_s Y \frac{e_2 s_2}{1 + s_2}.
\]  

(A.4)

To find the maximal value for \( d \) (see Results), parameters \( k_s, K_s, w_s, k_{e1}, k_{e2}, \) and \( Y \) are set to 1 (with exception of the models from group 2). Only the model specific parameters were changed for the optimization. For models in group 2, parameters \( k_2, k_{e2}, \) and the parameter for induction \( K_i^* \) (see below) were chosen in such a way, that growth on the less preferred substrate is still possible.

For metabolites with a fast dynamics, such as \( X_1, X_2 \) and \( M \), one obtains for the basic model by applying the quasi-steady-state assumption:

\[
\begin{align*}
  x_1 &= \frac{e_1 s_1}{1 + s_1}, & x_2 &= \frac{e_2 s_2}{1 + s_2}, & m &= x_1 + k_s x_2.
\end{align*}
\]  

(A.5)

Equations (A.2) together with (A.5) represent a system of differential equations that can be solved when kinetic parameters are plugged in.

A.2 Detailed description of model ensemble

In this section we give a detailed description of the models in the ensemble, by specifying which equations change with respect to the (rescaled) model structure in Supplementary Material A.1. In order to break the symmetry between the two substrate pathways, so that the models are able to produce a diauxic growth pattern, only a single parameter, function, or condition was changed in every case. The simulation results are shown for each model, starting from initial conditions in which the substrate concentrations are equal. The parameter values used are those maximizing the diauxic growth index defined by Equation (13) in the main text.

Constraint-based models

Model C1: FBA

The stoichiometry of the basic constraint-based model structure, given by Equations (1), (2), (11), and (12) in the main text, does not allow to break the symmetry between the two pathways and produce diauxic growth. However, motivated by the observed growth behaviour of *E. coli* in a minimal medium with glucose and acetate, a slight modification of the structure of the reaction network is sufficient to achieve this (Figure A.1). In particular, we use the following model:
\[ N' \vec{x} = \begin{bmatrix} h(S_1) & -1 & 0 & 0 & 0 \\ 0 & 0 & 1 & h(S_2) & -1 \\ 0 & 1 & -1 & 0 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ r_{d1} \\ r_{d2} \\ E_2 \\ r_b \end{bmatrix} = 0. \] (A.6)

**Model C2: regulatory FBA**

The regulatory constraints in regulatory FBA (rFBA) are modelled by logic rules relating environmental conditions to cellular responses, in particular the expression or activity of certain enzymes. For our model, we adapted a rule proposed in [1] for the growth of *E. coli* on glucose and lactose: if *S_1* is present then *E_2* is not present. The addition of this rule to the FBA model makes diauxic growth possible: the enzyme for *S_2* uptake in the model is set to zero \( e_2 = 0 \), if the glucose concentration is larger than a certain threshold value (Figure A.2).

**Model C3: molecular crowding**

The idea behind this modelling approach is that enzymes incorporated into the cell membrane occupy a certain fraction \( s \) of the cell volume. This results in an additional constraint on the enzyme concentrations [2], given by

\[ \nu_1 e_1 + \nu_2 e_2 \leq s \, \text{Vol}, \] (A.7)
where $\nu_1$ and $\nu_2$ are crowding coefficients and $\text{Vol}$ is the maximal volume of the cell. Figure A.3 shows the reaction scheme and the simulation results obtained when adding Equation A.7 to the FBA model.

![Figure A.3 Model C3. Left: reaction scheme. Right: simulation results for substrate $S_1$ (blue), substrate $S_2$ (red), and biomass $B$ (black). The membrane space occupied by enzymes gives rise to an additional constraint.](image)

**Model C4: costs and benefits of enzymes**

In this model variant, the costs to make enzymes and the benefits obtained (e.g., increased extraction of energy from nutrients) are taken into account [3]. For example, the higher costs of a pathway (ATP necessary for enzyme synthesis) could be balanced by the higher benefits it yields (ATP generated). Costs and benefits are limited to a certain maximum amount $C_0$:

$$
\begin{bmatrix}
\alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 & \alpha_5
\end{bmatrix}
\begin{bmatrix}
e_1 \\
r_{d1} \\
e_2 \\
r_{d2} \\
r_b
\end{bmatrix}
\leq C_0,
\tag{A.8}
$$

where $\alpha_i$ are cost coefficients. Rates of reactions for which the costs exceed the benefits (more ATP consumed than produced) have positive coefficients, whereas rates with higher benefits than costs (more ATP produced than consumed) have negative coefficients. In this example, we have $\alpha_1 > 0$, $\alpha_2 < 0$, $\alpha_3 > 0$, $\alpha_4 < 0$, and $\alpha_5 > 0$ (to reduce the number of freely selectable parameters for this model, we set $\alpha_1 = 1$, $\alpha_2 = -1$, $\alpha_4 = -1$, and $\alpha_5 = 0$. In this way, the model specific parameters that are changed in order to maximize $d$ are $\alpha_3$ and $C_0$). Equations (11) in the main text and (A.8) together define the extended FBA problem that can be solved by linear programming. Figure A.4 shows the reaction scheme and the simulation results.

**Kinetic models with growth dilution**

The four models in this group are all variants of the basic kinetic model structure given by Equations (1)-(7). In addition, they all take into account (indirect) transcription regulation of the enzymes by their corresponding intracellular metabolites (inducers). This is modelled by changing $f_i$ from its baseline value 1 to

$$
f_i = \frac{x_i^n}{x_i^n + K_i^*},
\tag{A.9}
$$

with parameters $n$ and $K_i^*$. 
Model N1: different maximum rates of enzyme synthesis

According to Narang and co-workers [4], different maximum synthesis rates $k_{e1}$ and $k_{e2}$ of the enzymes involved in the two pathways, while maintaining the same values for all other parameters, may lead to diauxic growth. Figure A.5 shows the reaction scheme and the simulation results obtained for such a model.

Model N2: different values for the initial enzyme concentrations

The system is simulated with the same set of parameters for the synthesis of the two enzymes, but the initial conditions $e_1(0) = e_1^0$ and $e_2(0) = e_2^0$ are different. Figure A.6 shows the reaction scheme and the simulation results.
Model N3: different affinity for inducers

The inducers may have a different affinity for their respective repressor proteins, as reflected in the values of $K_{r1}^*$ and $K_{r2}^*$, so that inducers differentially influence the synthesis of the two enzymes (Figure A.7).

Model N4: different maximum uptake rates for substrates

The turnover number of the transporters, and therefore the values of $k_{s1}$ and $k_{s2}$, may be different and result in diauxic growth behaviour (Figure A.8).
Kinetic models taking into account metabolic and genetic regulation

Model R1: inducer exclusion

Inducer exclusion is the classical control scheme to prevent the influx of carbohydrates that may act as inducers. In the case of glucose uptake in *E. coli*, the activity of permease LacY is known to be inhibited by the non-phosphorylated form of one of the PTS components, the enzyme EIIAGlc. In the simple model scheme used here, this is represented by an extension of the uptake rate $r_{s2}$ to $r_{s2}^*$, involving the component $X_1$:

$$r_{s2}^* = r_{s2} \frac{K_I}{K_I + x_1} = \frac{e_1 s_1 K_I}{1 + s_1 K_I + x_1}.$$  \hspace{1cm} (A.10)

In this case $X_1$ has two functions in the simple model: inducer for the first enzyme and effector for the second one. Figure A.9 shows the reaction scheme and the simulation results.

Model R2: transcription factor activation

Transcription factor activation is modelled in the following way. In *E. coli* flux through central metabolism is sensed; according to the ratio of PEP and pyruvate the degree of phosphorylation of the PTS is altered. If the PEP/pyruvate ratio is high, protein Cya is activated by the phosphorylated form of protein EIIAGlc. Due to the feed-forward structure in glycolysis (F1,6BP activates pyruvate kinase) a high
PEP/pyruvate ratio indicates low concentrations of central metabolites, whereas a low ratio corresponds to high concentrations. In the model, the rate of synthesis for the enzyme converting the second substrate is modified accordingly:

\[ r_{e2}^* = k_{e2} f_2 \frac{K_A}{K_A + m} \].

(A.11)

In this way central metabolite \( M \) acts as an inhibitor for gene expression of the second enzyme. Figure A.10 shows the reaction scheme and the simulation results.

---

**Models R3 and R4: central metabolite decreases/increases inducer concentration**

Besides the classical and well-known schemes discussed here, further model variants can be imagined. As described in the main text, control schemes in central metabolic pathways might have an influence on metabolites which in turn can act as regulators of global transcription factors. The rate of enzyme synthesis strongly depends on the concentration of the inducer. Two model variants are considered: (i) In the model, the drain from metabolite \( X_2 \) may be a target of control. If metabolite \( M \) acts as an activator of this reaction, then the concentration of \( X_2 \) decreases with higher \( M \), resulting in a lower rate of enzyme synthesis. (ii) Alternatively, \( M \) may act as an inhibitor of the reaction from \( X_1 \) to \( M \). In this case, \( X_1 \) increases due to a higher concentration of \( M \). Figures A.11 and A.12 show the reaction schemes for both model variants and the simulation results.
Resource allocation models

Models A1 and A2: distribution of macromolecular resources

In order to produce enzymes, resources in the form of amino acids as well as components of the transcriptional and translational apparatus are necessary. In the simple model, these different types of resources are all represented by the biomass compartment $B'$. Both model variants in this subsection are based on the availability of $B'$, but they can be distinguished by the type of underlying optimization problem.

In model A1, a certain fraction of $B'$ is available for transcription and translation of the enzymes (Figure A.13). As in the formulation of FBA, the growth rate is maximized. In this model, however, the growth rate is expressed as the sum of the substrate uptake rates:

$$r_{in} = r_s1 + r_s2. \quad (A.12)$$

As explained in the Methods section of the main text, the rates are expressed in terms of the amount of enzyme ($\xi = [e_1, e_2]^T$) and the corresponding optimization program reads:

$$\begin{align*}
\max \quad & r_{in} = \begin{bmatrix} h(s_1) & h(s_2) \end{bmatrix} \xi, \\
\text{s.t.} \quad & [1 \ 1] \xi \leq c \ b', 
\end{align*} \quad (A.13)$$

where $c$ represents the fraction of $b'$ available for the enzymes. This linear program can be solved at every time-point, for given values of $s_1$, $s_2$, and $b'$, and the enzyme concentrations thus obtained are used as input for the dynamics of the remaining variables. The symmetry between the two substrate pathways is broken by changing the maximal uptake rate $k_{s2}$ of the second substrate.

Model A2 is the dynamic variant of A1. In this case, the resources are consumed for the synthesis of the two enzymes (Figure A.14) and the objective is to maximize the biomass at $t_{end}$. In comparison with Equation (A.2), the functions $f_1$ and $f_2$ are changed to
Figure A.13 Model A1. Left: reaction scheme. Right: simulation results for substrate $S_1$ (blue), substrate $S_2$ (red), and biomass $B$ (black). The distribution of resources over the enzymes is shown by red circles.

\[
  f_1 = u b' \quad \text{and} \quad f_2 = (u_{\text{max}} - u) b'.
\]  
  \hspace{1cm} \text{(A.14)}

This allows the distribution of a certain fraction ($u_{\text{max}} < 1$) of $B'$ over the synthesis of the enzymes. The equation for the (scaled) biomass compartment $b'$ takes into account the drain of resources to enzyme synthesis:

\[
  \dot{b}' = m - (u_{\text{max}} + \mu) b', \quad b'(0) = b'_0.
\]  
  \hspace{1cm} \text{(A.15)}

Figure A.14 Model A2. Left: reaction scheme. Right: simulation results for substrate $S_1$ (blue), substrate $S_2$ (red), and biomass $B$ (black). The flow of resources to enzyme synthesis is shown by red circles.

The complete dynamic optimization program is then given by:

\[
  \begin{align*}
  \text{max} & \quad b(t_{\text{end}}), \\
  \text{s.t.} & \quad \dot{x} = f(x, u), \\
  & \quad m < m^*.
  \end{align*}
\]  
  \hspace{1cm} \text{(A.16)}

with $x$ are the state variables. The inequality constraint on $m$ in the last equation guarantees that the concentration of this internal metabolite remains within physiological bounds. When simulating the system, it turns out that the dynamics are very sensitive to the value of this parameter $m^*$. When choosing low values for $m^*$, a diauxic growth pattern occurs without a change in the other parameters.
Model A3: cybernetic modelling approach

Nearly thirty years ago, Ramkrishna and co-workers proposed the cybernetic modelling framework [5, 6]. Like in model A2, the underlying idea is to allocate resources to enzyme synthesis depending on the carbon influx, but without solving an explicit optimization problem. Two so-called cybernetic variables are defined: \( u \) and \( v \), where \( u_i \) represents the fractional allocation of resources to the synthesis of enzyme \( i \) given by \( u_i = r_{si} / (r_{s1} + r_{s2}) \) (matching law), and \( v_i \) represents enzyme activity control given by \( v_i = r_{si} / \max(r_{s1}, r_{s2}) \). To obtain diauxic growth, it is sufficient to consider only the control of enzyme synthesis (variables \( u_i \)). Figure A.15 shows the reaction scheme and the simulation results.

Models A4 and A5: competition for substrate transport resources

For the uptake of carbohydrates, energy in the form of ATP, a proton gradient or an internal metabolite is required (Figure A.16). Furthermore, some carbohydrates are taken up by a phosphotransferase system (PTS) in \( E. coli \) (Figure A.17). Therefore, two model variants are considered, one in which metabolite \( M \) is consumed as the energy source and one in which it used for the phosphorylation of transporter proteins. In order to compensate for the loss of \( M \) during substrate transport, in these models, the stoichiometry of the two reactions providing \( M \) from \( X_i \) is changed to 2 (one molecule of \( X_i \) provides two molecules of \( M \)). Notice that in these models the quasi-steady-state assumption for metabolite \( M \) is no longer valid and the differential equation instead of the algebraic equation for \( m \) is used. The equation for \( M \) read:

\[
\dot{m} = 2(x_1 + x_2) - m - r_{s1} - r_{s2}, \quad m(0) = m_0.
\]

In model A4, where metabolite \( M \) is used as the energy source, the uptake rates for the substrates read:

\[
r_{s1} = e_1 \frac{s_1}{1 + s_1 \frac{m}{K_{M1} + m}}.
\]

\[
r_{s2} = k^* e_2 \frac{s_2}{1 + S_2 \frac{m}{K_{M2} + m}}.
\]

The steady-state values for \( x_1 \) and \( x_2 \) change accordingly. In order to break the symmetry between the two pathways, we change parameter \( k^* \) to a value lower than 1.

In model A5, the carbohydrates are taken up by a PTS, a group translocation system generally involving a number of proteins in either phosphorylated or unphosphorylated form. In order to mimic the behaviour
of a PTS with the simple model structure given here, we consider a phosphorylated form $e_p$ and an unphosphorylated form $e$ of the enzymes. The kinetic expressions for the uptake rates read:

$$
\begin{align*}
    r_{s1} &= e_{p1} \frac{s_1}{1 + s_1}, \\
    r_{s2} &= e_{p2} \frac{s_2}{1 + S_2},
\end{align*}
$$

and the kinetic expressions for the regeneration of the phosphorylated forms read:

$$
\begin{align*}
    r_{m1} &= k_{p1} e_1 m - k_{p_{m1}} e_{p1}, \\
    r_{m2} &= k_{p2} e_2 m - k_{p_{m2}} e_{p2},
\end{align*}
$$

For the unphosphorylated enzymes $e_1$ and $e_2$, only weak induction is taken into account. A difference in value of parameters $k_{pi}$ allows to break the symmetry between the two substrate pathways. Induction and dilution are taken into account in the equations for the unphosphorylated proteins. The modified equations for the system read:

$$
\begin{align*}
    \dot{e}_1 &= k_{e1} f_1 + r_{s1} - r_{m1} - \mu e_1, \quad e_1(0) = e_{10}, \\
    \dot{e}_2 &= k_{e2} f_2 + r_{s2} - r_{m2} - \mu e_2, \quad e_2(0) = e_{20}, \\
    \dot{m} &= 2(x_1 + x_2) - m - r_{m1} - r_{m2}, \quad m(0) = m_0 \\
    \dot{e}_{p1} &= r_{m1} - r_{s1}, \quad e_{p1}(0) = e_{p10} \\
    \dot{e}_{p2} &= r_{m2} - r_{s2}, \quad e_{p2}(0) = e_{p20}
\end{align*}
$$

(A.21)
Figure A.17 Model A5. Left: reaction scheme. Right: simulation results for substrate $S_1$ (blue), substrate $S_2$ (red), and biomass $B$ (black). Both PTS transport systems need $M$ to take up the substrates.

**Model A6: maximizing time**

As discussed in [7], a possible cellular strategy is to maximize survival, which can be formulated as follows in the context of our modelling framework:

$$
\begin{align*}
\text{max} & \quad t_{\text{end}}, \\
\text{s.t.} & \quad \dot{x} = f(x, u), \\
& \quad b' > b^*,
\end{align*}
$$

where $x$ represents the state variables in the model and where the last equation is a constraint to have the main biomass compartment larger than a threshold value. To solve the optimization problem, the Matlab package DOTcvp was used.

Figure A.18 Model A6. Left: reaction scheme. Right: simulation results for substrate $S_1$ (blue), substrate $S_2$ (red), and biomass $B$ (black). The lifetime $t_{\text{end}}$ is maximized.

**A.3 Results of cluster analysis**

Figure A.19 shows the dendrograms for the experiment with a high initial enzyme concentration and Figure A.20 shows the dendrograms for the pulse experiment. Moreover, Figure A.21 shows the time-courses of the mean of each cluster as well as of the individual models (in grey). Table A.1 summarizes how the models are divided between the clusters in the case of the experiment with a high initial enzyme concentration, while Table A.2 provides the same information for the pulse experiment.
We describe the procedure in more detail for the pulse experiment: the system is simulated over a short time period in the presence of lactose (substrate 2) and then the initial condition for glucose (substrate 1) is changed. The predicted time-courses of the substrate lactose and the enzyme for lactose uptake are stored in matrices for all model variants. In order to perform hierarchical clustering, the Matlab command “linkage” with options “ward” and “euclidean” is used. Finally the dendrogram is plotted.

![Dendrograms](image)

**Figure A.19** Dendrograms for the experiment with a high initial enzyme concentration (top: substrate, bottom: enzyme).

We find a qualitative agreement with the experimental data for the following clusters:

- **Experiment with a high initial enzyme concentration:**
  - Substrate: Cluster 1
  - Enzyme: Clusters 1, 3, 5, and 6

- **Pulse experiment:**
  - Substrate: Clusters 2 and 3
  - Enzyme: Clusters 4, 5, and 6

As discussed in the main text, taking the intersection of the clusters consistent with the experimental data confirms that model variant R1 (inducer exclusion) is the main mechanism for glucose-lactose diauxic growth behaviour.

Figure A.21  A: Substrate (left) and enzyme (right) time-courses for the experiment with a high initial enzyme concentration. B: Idem for the pulse experiment. Each numbered plot corresponds to a cluster used in Tables A.1 and A.2.
A.4 Model fitting

The best set of parameters to describe the experimental data was obtained with a genetic algorithm with Matlab as describe in [8]. Parameters used are given in the following:

- `populationSize = 40;`
- `numberOfGenes = 40;`
- `crossoverProbability = 0.8;`
- `mutationProbability = 0.025;`
- `tournamentSelectionParameter = 0.75;`
- `numberOfGenerations = 30;`

The range for each parameter was selected independently.

Figure A.22 shows the fit of the models in the ensemble with the experimental data of the glucose-lactose diauxie from [9] and a statistical evaluation of the fit ($\chi^2$-test). For glucose, 5 data points and for lactose and biomass 12 data points were used for model fitting. The measured error was estimated as 10% for glucose and 15% for lactose and biomass.

![Model fitting results](image-url)

*Figure A.22* Upper plots: comparison of the predicted time-courses for all fitted models (solid curves) with the experimentally-measured time-courses of glucose, lactose, and biomass [9]. Lower plot: values of the objective function (bars) and threshold of $\chi^2$ statistics (solid lines).
